Abstract. Improvement in information retrieval systems is largely dependent on the ability to evaluate them. In order to assess the effectiveness of a retrieval system, test collections are needed. In traditional approaches users or hired evaluators provide manual assessments of relevance. However this does not scale with the complexity and heterogeneity of available digital information. This paper proposes to use topic ontologies and semantic similarity data to alleviate the efforts needed by human assessors to evaluate the rapidly expanding set of competing information retrieval methods. After providing experimental evidence supporting the validity of our approach we illustrate its application with an example in which the proposed evaluation procedure is used to assess the effectiveness of topical retrieval systems.

Keywords: information retrieval, evaluation, topic ontologies, semantic similarity.

1 Introduction

Building test collections is a crucial aspect of information retrieval experimentation. The predominant approach used for the evaluation of information retrieval systems, first introduced in the Cranfield experiments [9], requires a collection of documents, a set of topics or queries, and a set of relevance judgments created by human assessors who mark the documents as relevant or irrelevant to a particular topic or query. However, reading large sets of document collections and judging them is expensive, especially when these documents cover diverse topics. In light of this difficulty a number of frameworks for automatic or semiautomatic evaluation have been proposed.

A common approach that has been applied in automatic evaluations is based on the use of pseudo-relevance judgments automatically computed from the retrieved documents themselves. A simple framework based on these ideas is the one proposed in [14]. In this approach the vector space model is used to represent queries and results. Then, the relevance of each result is estimated based on the similarity between the query vector and the result vector. Another approach for automatic evaluation uses a list of terms that are believed to be relevant to a query (onTopic list) and a list of irrelevant terms (offTopic list) [3]. This evaluation method scores every result $d$ by considering the appearances of onTopic and offTopic terms in $d$. The authors show that their method is
highly correlated with official TREC collections. Click-through data have also been exploited to assess the effectiveness of retrieval systems [16]. However, studies suggest that there is a bias inherent in this data: users tend to click on highly ranked documents regardless of their quality [6].

Editor-driven topic ontologies such as ODP\(^1\) (Open Directory Project) have enabled the design of automatic evaluation frameworks. In [5] the ODP ontology is used to find sets of pseudo-relevant documents assuming that entries are relevant to a given query if their editor-entered titles match the query. Additionally, all entries in a leaf-level taxonomy category are relevant to a given query if the category title matches the query. Haveliwala et al. [12] defines a partial ordering on documents from the ODP ontology based on the ODP hierarchical structure. The inferred ordering is then used as a pre-compiled test collection to evaluate several strategies for similarity search on the Web. Menczer adapted Lin’s information theoretic measure of similarity [15] and computed it over a large number of pairs of pages from ODP [23]. Lin’s measure of similarity has several desirable properties and a solid theoretical justification. However, as it was the case for Haveliwala et al.’s ordering, the proposed measure is defined only in terms of the hierarchical component of the ODP ontology and fails to capture many semantic relationships induced by the ontology’s non-hierarchical components (symbolic and related links). As a result, according to this measure, the similarity between pages in topics that belong to different top-level categories is zero even if the topics are clearly related. This yielded an unreliable picture when all topics were considered.

In light of this limitation Maguitman et al. [20] proposed an information theoretic measure of semantic similarity that generalizes Lin’s tree-based similarity to the case of a graph. This measure of similarity can be applied to objects stored in the nodes of arbitrary graphs, in particular topical ontologies that combine hierarchical and non-hierarchical components such as Yahoo!, ODP and their derivatives. Therefore, it can be usefully exploited to derive semantic relationships between millions of Web pages stored in these topical ontologies, giving way to the design of more precise automatic evaluation framework than those that are based only on the hierarchical component of these ontologies.

The goal of this paper is to further evaluate this graph-based information theoretic measure of semantic similarity and to illustrate its application in the evaluation of topical search systems.

2 Topic Ontologies and Semantic Similarity

Web topic ontologies are means of classifying Web pages based on their content. In these ontologies, topics are typically organized in a hierarchical scheme in such a way that more specific topics are part of more general ones. In addition, it is possible to include cross-references to link different topics in a non-hierarchical scheme. The ODP ontology is the largest human-edited directory of the Web. It classifies millions of pages into a topical ontology combining a hierarchical and non-hierarchical scheme. This topical directory can be used to measure semantic relationships among massive numbers of pairs of Web pages or topics.

---

Many measures have been developed to estimate semantic similarity in a network representation. Early proposals have used path distances between the nodes in the network (e.g., [25]). These frameworks are based on the premise that the stronger the semantic relationship of two objects, the closer they will be in the network representation. However, as it has been discussed by a number of sources, issues arise when attempting to apply distance-based schemes for measuring object similarities in certain classes of networks where links may not represent uniform distances (e.g., [26]).

To illustrate the limitations of the distance-based schemes take the ODP sample shown in figure 1. While the edge-based distance between the topics JAPANESE GARDENS and COOKING is the same as the one between the topics JAPANESE GARDENS and BONSAI AND SUISEKI, it is clear that the semantic relationship between the second pair is stronger than the semantic relationship between the first pair. The reason for this stronger semantic relationship lays in the fact that the lowest common ancestor of the topics JAPANESE GARDENS and BONSAI AND SUISEKI is the topic GARDENS, a more specific topic than HOME, which is the lowest common ancestor of the topics JAPANESE GARDENS and COOKING. To address the issue of specificity, some proposals estimate semantic similarity in a taxonomy based on the notion of information content [26, 15].

In information theory [10], the information content of a class or topic $t$ is measured by the negative log likelihood, $- \log \Pr[t]$, where $\Pr[t]$ represents the prior probability that any object is classified under topic $t$. In practice $\Pr[t]$ can be computed for every topic $t$ in a taxonomy by counting the fraction of objects stored in the subtree rooted at $t$ (i.e., objects stored in node $t$ and its descendants) out of all the objects in the taxonomy.

According to Lin’s proposal [15], the semantic similarity between two topics $t_1$ and $t_2$ in a taxonomy is measured as the ratio between the meaning of their lowest common ancestor and their individual meanings. This can be expressed as follows:

$$
\sigma_T^S(t_1, t_2) = \frac{2 \cdot \log \Pr[t_0(t_1, t_2)]}{\log \Pr[t_1] + \log \Pr[t_2]}
$$

where $t_0(t_1, t_2)$ is the lowest common ancestor topic for $t_1$ and $t_2$ in the tree. Given a document $d$ classified in a topic taxonomy, we use $\text{topic}(d)$ to refer to the topic node containing $d$. Given two documents $d_1$ and $d_2$ in a topic taxonomy the semantic simi-
larity between them is estimated as $\sigma^T_s(topic(d_1), topic(d_2))$. To simplify notation, we use $\sigma^T_s(d_1, d_2)$ as a shorthand for $\sigma^T_s(topic(d_1), topic(d_2))$.

![Fig. 2. Illustration of a simple topic ontology.](image)

An important distinction between taxonomies and general topic ontologies such as ODP is that edges in a taxonomy are all “is-a” links, while in ODP edges can have diverse types such as “is-a”, “symbolic” and “related”. The existence of “symbolic” and “related” edges should be given due consideration as they have important implication in the semantic relationships between the topics linked by them. Consider for example the portion of the ODP shown in figure 2. If only the taxonomy edges are considered, then the semantic similarity between the topics BONS AI AND SUIS EKI and BONS AI would be zero, which does not reflect the strong semantic relationship existing between both topics.

To address this limitation Maguitman et al. [20] defined a graph-based semantic similarity measure $\sigma^G_s$ that generalizes Lin’s tree-based similarity $\sigma^T_s$ to exploit both the hierarchical and non-hierarchical components of an ontology. In the following we recall the definitions that are necessary to characterize $\sigma^G_s$.

### 2.1 Defining and Computing a Graph-Based Semantic Similarity Measure

A topic ontology graph is a graph of nodes representing topics. Each node contains objects representing documents (Web pages). An ontology graph has a hierarchical (tree) component made by “is-a” links, and a non-hierarchical component made by cross links of different types.

For example, the ODP ontology is a directed graph $G = (V, E)$ where:
– \( V \) is a set of nodes, representing topics containing documents;
– \( E \) is a set of edges between nodes in \( V \), partitioned into three subsets \( T, S, \) and \( R \), such that:
  • \( T \) corresponds to the hierarchical component of the ontology,
  • \( S \) corresponds to the non-hierarchical component made of “symbolic” cross-links,
  • \( R \) corresponds to the non-hierarchical component made of “related” cross-links.

In addition, each node \( t \in V \) contains a set of objects. We use \(|t|\) to refer to the number of objects stored in node \( t \).

The extension of \( \sigma^T_i \) to an ontology graph raises several questions: (1) how to deal with edges of diverse type in an ontology, (2) how to find the most specific common ancestor of a pair of topics, and (3) how to extend the definition of subtree rooted at a topic for the ontology case.

Different types of edges have different meanings and should be used accordingly. One way to distinguish the role of different edges is to assign them weights, and to vary these weights according to the edge’s type. The weight \( w_{ij} \in [0, 1] \) for an edge between topic \( t_i \) and \( t_j \) can be interpreted as an explicit measure of the degree of membership of \( t_j \) in the family of topics rooted at \( t_i \). The weight setting we have adopted for the edges in the ODP graph is as follows: \( w_{ij} = \alpha \) for \((i, j) \in T \), \( w_{ij} = \beta \) for \((i, j) \in S \), and \( w_{ij} = \gamma \) for \((i, j) \in R \). We set \( \alpha = \beta = 1 \) because symbolic links seem to be treated as first-class taxonomy (“is-a”) links in the ODP Web interface.

Since duplication of URLs is disallowed, symbolic links are a way to represent multiple memberships, for example the fact that the pages in topic SHOPPING/HOME AND GARDEN/PLANTS/TREES/BONSAI also belong to topic HOME/GARDENS/SPECIALIZED TECHNIQUES/BONSAI AND SUISEKI. On the other hand, we set \( \gamma = 0.5 \) because related links are treated differently in the ODP Web interface, labeled as “see also” topics. Intuitively the semantic relationship is weaker. Different weighting schemes could be explored.

As a starting point, let \( w_{ij} > 0 \) if and only if there is an edge of some type between topics \( t_i \) and \( t_j \). However, to estimate topic membership, transitive relations between edges should also be considered. Let \( t_i \) be the family of topics \( t_j \) such that there is a direct path in the graph \( G \) from \( t_i \) to \( t_j \), where at most one edge from \( S \) or \( R \) participates in the path. We refer to \( t_i \) as the cone of topic \( t_j \). Because edges may be associated with different weights, different topics \( t_j \) can have different degree of membership in \( t_i \).

In order to make the implicit membership relations explicit, we represent the graph structure by means of adjacency matrices and apply a number of operations to them. A matrix \( T \) is used to represent the hierarchical structure of an ontology. Matrix \( T \) codifies edges in \( T \) and is defined so that \( T_{ij} = \alpha \) if \((i, j) \in T \) and \( T_{ij} = 0 \) otherwise. We use \( T \) with 1s on the diagonal (i.e., \( S_{ii} = 01 \) for all \( i \)). Additional adjacency matrices are used to represent the non-hierarchical components of an ontology. For the case of the ODP graph, a matrix \( S \) is defined so that \( S_{ij} = \beta \) if \((i, j) \in S \) and \( S_{ij} = 0 \) otherwise. A matrix \( R \) is defined analogously, as \( R_{ij} = \gamma \) if \((i, j) \in R \) and \( R_{ij} = 0 \) otherwise.

Consider the operation \( \lor \) on matrices, defined as \([A \lor B]_{ij} = \max(A_{ij}, B_{ij})\), and let \( G = T \lor S \lor R \). Matrix \( G \) is the adjacency matrix of graph \( G \) augmented with 1s on the diagonal.
We will use the MaxProduct fuzzy composition function \( \odot \) [13] defined on matrices as follows:
\[
[A \odot B]_{ij} = \max_k (A_{ik} \cdot B_{kj}).
\]
Let \( T^{(0)} = T \) and \( T^{(r+1)} = T^{(0)} \odot T^{(r)} \). We define the closure of \( T \), denoted \( T^+ \) as follows:
\[
T^+ = \lim_{r \to \infty} T^{(r)}.
\]
In this matrix, \( T^+_{ij} = 1 \) if \( t_j \in \text{subtree}(t_i) \), and \( T^+_{ij} = 0 \) otherwise.

Finally, we compute the matrix \( W \) as follows:
\[
W = T^+ \odot G \odot T^+.
\]

The element \( W_{ij} \) can be interpreted as a fuzzy membership value of topic \( t_j \) in the cone \( t_i \). Therefore we refer to \( W \) as the fuzzy membership matrix of \( G \).

The semantic similarity between two topics \( t_1 \) and \( t_2 \) in an ontology graph can now be estimated as follows:
\[
\sigma^G_s(t_1, t_2) = \max_k \frac{2 \cdot \min(W_{k1}, W_{k2}) \cdot \log \Pr[t_k]}{\log(\Pr[t_1|t_k] \cdot \Pr[t_k]) + \log(\Pr[t_2|t_k] \cdot \Pr[t_k])}.
\]

The probability \( \Pr[t_k] \) represents the prior probability that any document is classified under topic \( t_k \) and is computed as:
\[
\Pr[t_k] = \frac{\sum_{t_j \in V} (W_{kj} \cdot |t_j|)}{|U|},
\]
where \(|U|\) is the number of documents in the ontology. The posterior probability \( \Pr[t_i|t_k] \) represents the probability that any document will be classified under topic \( t_i \) given that it is classified under \( t_k \), and is computed as follows:
\[
\Pr[t_i|t_k] = \frac{\sum_{t_j \in V} (\min(W_{ij}, W_{kj}) \cdot |t_j|)}{\sum_{t_j \in V} (W_{kj} \cdot |t_j|)}.
\]

The proposed definition of \( \sigma^G_s \) is a generalization of \( \sigma^T_s \). In the special case when \( G \) is a tree (i.e., \( S = R = \emptyset \)), then \( t_i \) is equal to \( \text{subtree}(t_i) \), the topic subtree rooted at \( t_i \), and all topics \( t \in \text{subtree}(t_j) \) belong to \( t_i \) with a degree of membership equal to 1. If \( t_k \) is an ancestor of \( t_1 \) and \( t_2 \) in a taxonomy, then \( \min(W_{k1}, W_{k2}) = 1 \) and \( \Pr[t_i|t_k] = \Pr[t_i] \) for \( i = 1, 2 \). In addition, if there are no cross-links in \( G \), the topic \( t_k \) whose index \( k \) maximizes \( \sigma^G_s(t_1, t_2) \) corresponds to the lowest common ancestor of \( t_1 \) and \( t_2 \).

The proposed semantic similarity measure \( \sigma^G_s \) as well as Lin’s similarity measure \( \sigma^T_s \) was applied to the ODP ontology and computed for more than half million topic nodes. As a result, we obtained the semantic similarity values \( \sigma^G_s \) and \( \sigma^T_s \) for more than \( 1.26 \times 10^{12} \) pairs of pages.\(^3\) We found out that \( \sigma^G_s \) and \( \sigma^T_s \) are moderately correlated.

\(^2\) With our choice of weights, MaxProduct composition is equivalent to MaxMin composition.

\(^3\) This required a computational effort of approximately 5,000 CPU hours using 20 nodes of a IU’s AVIDD super-computing facility, resulting in 1 TB of data.
Further analysis indicated that the two measures give us estimates of semantic similarity that are quantitatively and qualitatively different (see [20] for details).

3 Validation

In [20] we reported a human-subject experiment to compare the proposed semantic similarity measure \( \sigma^G_s \) against Lin’s measure \( \sigma^T_s \). The goal of that experiment was to contrast the predictions of the two semantic similarity measures against human judgments of Web pages relatedness. To test which of the two methods was a better predictor of subjects’ judgments of Web page similarity we considered the selections made by each of the human-subjects and computed the percentage of correct predictions made by the two methods. Measure \( \sigma^G_s \) was a better estimate of human-predictions in 84.65% of the cases while \( \sigma^T_s \) was a better predictor in 5.70% of the cases (the remaining 9.65% of the cases were undecided).

Although \( \sigma^G_s \) significantly improves the predictions made by \( \sigma^T_s \), the study outlined above focuses on cases where \( \sigma^G_s \) and \( \sigma^T_s \) disagree. Thus it tells us that \( \sigma^G_s \) is more accurate than \( \sigma^T_s \) but is too biased to satisfactorily answer the broader question of how well \( \sigma^G_s \) predicts assessments of semantic similarity by human subjects in general.

3.1 Validation of \( \sigma^G_s \) as a Ranking Function

To provide stronger evidence supporting the effectiveness of \( \sigma^G_s \) as a predictor of human assessments of similarity, we conducted a new experiment. The goal of this new experiment was to determine if the rankings induced by \( \sigma^G_s \) were in accordance with rankings produced by humans.

Twenty volunteer subjects were recruited to answer questions about similarity rankings for Web pages. For each question, they were presented with a target Web page and three candidate Web pages that had to be ranked based on their similarity to the target page. The subjects had to answer by sorting the three candidate pages. A total of 6 target Web pages randomly selected from the ODP directory were used for the evaluation. For each target Web page we presented a series of 3 triplets of candidate Web pages. The candidate pages were selected with controlled differences in their semantic similarity to the target page, ensuring that there was a difference in \( \sigma^G_s \) of at least 0.1 among them. To ensure that the participants made their choice independently of the questions already answered, we randomized the order of the options. The result of the experiment was an average Spearman rank correlation coefficient \( \rho = 0.73 \).

4 Evaluating Topical Search using ODP and Semantic Similarity

In this work we define topical search as a process which goal is to retrieve resources relevant to a thematic context (e.g., [18]). The thematic context can consist of a document that is being editing or a Web page that is being visited. The availability of powerful search interfaces makes it possible to develop efficient topical search systems. Access to relevant material through these interfaces requires the submission of queries. As a consequence, learning to automatically formulate effective topical queries is an important research problem in the area of topical search.

In order to determine if a topical search system is effective we need to identify the set of relevant documents for a given topic. The classification of Web pages into topics
as well as their semantic similarity derived from topical ontologies can be usefully exploited to build a test collection. In particular, these topical ontologies serve as a means to identify relevant (and partially relevant) documents for each topic. Once these relevance assessments are available, appropriate performance metrics that reflect different aspects of the effectiveness of topical search systems can be computed.

Consider the ODP topic ontology. Let $R_t$ be the set containing all the documents associated with the subtree rooted at topic $t$ (i.e., all documents associated with topic $t$ and its subtopics). In addition, other topics in the ODP ontology could be semantically similar to $t$ and hence the documents associated with these topics are partially relevant to $t$. We use $\sigma_G(t, \text{topic}(d))$ to refer to the semantic similarity between topic $t$ and the topic assigned to document $d$. Additionally, we use $A_q$ to refer to the set of documents returned by a search system using $q$ as a query, while $A_{q10}$ is the set of top-10 ranked documents returned for query $q$.

4.1 Evaluation Metrics

In order to evaluate the performance of a topical search system using the ODP ontology we could use the following metrics which are taken directly or are adapted from classical information retrieval performance evaluation metrics [4].

**Precision.** This well-known performance evaluation metric is computed as the fraction of retrieved documents which are known to be relevant to topic $t$:

$$\text{Precision}(q, t) = \frac{|A_q \cap R_t|}{|A_q|}.$$  

**Semantic Precision.** As mentioned above, other topics in the ontology could be semantically similar (and therefore partially relevant) to topic $t$. Therefore, we propose a measure of semantic precision defined as follows:

$$\text{Precision}_S(q, t) = \sum_{d \in A_q} \sigma_G(t, \text{topic}(d))/|A_q|.$$  

Note that for all $d \in t$ we have that $\sigma_G(t, \text{topic}(d)) = 1$. Consequently $\text{Precision}_S$ can be seen as a generalization of $\text{Precision}$, where $\text{Precision}_S$ takes into account not only relevant but also partially relevant documents.

**Precision at rank 10.** Since topical retrieval typically results in a large number of matches, sorted according to some criteria, rather than looking at precision, we can take precision at rank 10, which is computed as the fraction of the top 10 retrieved documents which are known to be relevant:

$$\text{Precision}@10(q, t) = \frac{|A_{q10} \cap R_t|}{|A_{q10}|}.$$  

**Semantic Precision at rank 10.** We compute semantic precision at rank 10 as a generalization of $\text{Precision}@10$ by considering the fraction of the top ten retrieved documents which are known to be relevant or partially relevant to $t$:

$$\text{Precision}_S@10(q, t) = \sum_{d \in A_{q10}} \sigma_G(t, \text{topic}(d))/|A_{q10}|.$$
Recall. We adopt the traditional performance measure of recall [4] as another criteria for evaluating query effectiveness. For a query \( q \) and a topic \( t \), recall is defined as the fraction of relevant documents \( R_t \) that are in the answer set \( A_q \):

\[
\text{Recall}(q, t) = \frac{|A_q \cap R_t|}{|R_t|}.
\]

Harmonic Mean. Finally we use the function \( F\text{-score} \), which is the weighted harmonic mean of precision and recall [4]:

\[
F\text{-score}(q, t) = \frac{2 \cdot \text{Precision}(q, t) \cdot \text{Recall}(q, t)}{\text{Precision}(q, t) + \text{Recall}(q, t)}.
\]

Other metrics could be used to compute a weighted harmonic mean. For example, we can compute \( F\text{-score}_{10} \) as follows:

\[
F\text{-score}_{10}(q, t) = \frac{2 \cdot \text{Precision}_{10}(q, t) \cdot \text{Recall}(q, t)}{\text{Precision}_{10}(q, t) + \text{Recall}(q, t)}.
\]

In addition, we propose a weighted harmonic mean that takes into consideration partially relevant material by aggregating \( \text{Precision}_S \) and \( \text{Recall} \) as follows:

\[
F\text{-score}_S(q, t) = \frac{2 \cdot \text{Precision}_S(q, t) \cdot \text{Recall}(q, t)}{\text{Precision}_S(q, t) + \text{Recall}(q, t)}.
\]

Analogously, we can define \( F\text{-score}_{S}@10(q, t) \) as follows:

\[
F\text{-score}_S@10(q, t) = \frac{2 \cdot \text{Precision}_S@10(q, t) \cdot \text{Recall}(q, t)}{\text{Precision}_S@10(q, t) + \text{Recall}(q, t)}.
\]

4.2 A Short Description of the Evaluated Systems

In illustrating the application of the proposed evaluation framework we will focus on assessing the performance of supervised topical search systems. Supervised systems require explicit relevance feedback, which is typically obtained from users who indicate the relevance of each of the retrieved documents. The best-known algorithm for relevance feedback has been proposed by Rocchio [27]. Given an initial query vector \( \vec{q} \) a modified query \( \vec{q}_m \) is computed as follows:

\[
\vec{q}_m = \alpha \vec{q} + \beta \sum_{d_j \in R_t} \vec{d}_j - \gamma \sum_{d_j \in I_t} \vec{d}_j.
\]

where \( R_t \) and \( I_t \) are the sets of relevant and irrelevant documents respectively and \( \alpha \), \( \beta \) and \( \gamma \) are tuning parameters. A common strategy is to set \( \alpha \) and \( \beta \) to a value greater than 0 and \( \gamma \) to 0, which yields a positive feedback strategy. When user relevance judgments are unavailable, the set \( R_t \) is initialized with the top \( k \) retrieved documents and \( I_t \) is set to \( \emptyset \). This yields an unsupervised relevance feedback method.
The Bo1 and Bo1* Methods. A successful generalization of Rocchio’s method is the Divergence from Randomness mechanism with Bose-Einstein statistics (Bo1) [2]. To apply this model, we first need to assign weights to terms based on their informativeness. This is estimated by the divergence between the term distribution in the top-ranked documents and a random distribution as follows:

\[ w(t) = tf_x \log_2 \left( 1 + \frac{P_n}{P_n} \right) + \log_2(1 + P_n) \]

where \( tf_x \) is the frequency of the query term in the top-ranked documents and \( P_n \) is the proportion of documents in the collection that contains \( t \). Finally, the query is expanded by merging the most informative terms with the original query terms.

The main problem of the Bo1 query refinement method is that its effectiveness is correlated with the quality of the top-ranked documents returned by the first-pass retrieval. If relevance feedback is available, it is possible to implement a supervised version of the Bo1 method, which we will refer to as Bo1*. This new method is identical to the Bo1 method except that rather than considering the top-ranked documents to assign weights to terms, we look only at the top-ranked documents which are known to be relevant. Once the initial queries have been refined by applying the Bo1* method on the training set, they can be used on a different set. The Bo1* method can be regarded as a supervised version of the Bo1.

Multi-Objective Evolutionary Algorithms for Topical Search. In [8] we presented a novel approach to learn topical queries that simultaneously satisfy multiple retrieval objectives. The proposed methods consist in training a Multi-Objective Evolutionary Algorithm (MOEA) that incrementally moves a population of queries towards the proposed objectives.

In order to run a MOEA for evolving topical queries we need to generate an initial population of queries. Each chromosome represents a query and each term corresponds to a gene that can be manipulated by the genetic operators. The vector-space model is used in this approach [4] and therefore each query is represented as a vector in term space.

In our tests, we used a portion of the ODP ontology to train the MOEAs and a different portion to test it. The initial queries were formed with a fixed number of terms extracted from the topic description available from the ODP. Documents from the training portion of ODP were used to build a training index, which was used to implement a search interface. Following the classical steps of evolutionary algorithms, the best queries have higher chances of being selected for subsequent generations and therefore as generations pass, queries associated with improved search results will predominate. Furthermore, the mating process continually combines these queries in new ways, generating ever more sophisticated solutions.

Although we have analyzed different evolutionary algorithms techniques following the above general schema, we will limit the evaluation reported here to two strategies:

– NSGA-II: Multiple objectives are simultaneously optimized with a different fitness function used for each objective. For this purpose we used NSGA-II (Nondominated Sorting Genetic Algorithm – II) [11], a MOEA based on the Pareto dominance concept (dominance is a partial order that could be established among vectors
A. G. Maguitman, R. L. Cecchini, C. M. Lorenzetti & F. Menczer

defined over an n-dimensional space). In our tests, NSGA-II attempted to maximize *Precision@10* and *Recall*.

- **Aggregative MOEA**: A single fitness function that aggregates multiple objectives as a scalar value is used. For that purpose, we have used the *F-score@10* measure introduced earlier.

Due to space limitations we refer the reader to [8] for details on the implementation of these MOEA strategies for topical search and focus here on how their performance was assessed using the proposed evaluation framework.

### 4.3 Results

Our evaluations were run on 448 topics from the third level of the ODP hierarchy. For each topic we collected all of its URLs as well as those in its subtopics. The language of the topics used for the evaluation was restricted to English and only topics with at least 100 URLs were considered. The total number of collected pages was more than 350,000. We divided each topic in such a way that 2/3 of its pages were used to create a training index and 1/3 to create a testing index. The Terrier framework [24] was used to index these pages and to create a search engine. We used the stopword list provided by Terrier and Porter stemming was performed on all terms. In addition we took advantage of the ODP ontology structure to associate a semantic similarity measure to each pair of topics. In our evaluations we compared the performance of four topical search strategies that consisted in (1) queries generated directly from the initial topic description (baseline); (2) queries generated using the Bo1⋆ query-refinement technique reviewed earlier in this article; (3) queries evolved using NSGA-II; and (4) queries evolved using the aggregative MOEA strategy.

Out of the 448 topics used to populate the indices, a subset of 110 randomly selected topics was used to evaluate the supervised topical search systems discussed in the previous section. For the training stage we ran the MOEAs with a population of 250 queries, a crossover probability of 0.7 and a mutation probability of 0.03. The selection of values for these parameters was guided by previous studies [7]. For each analyzed topic the population of queries was randomly initialized using its ODP description. The size of each query was a random number between 1 and 32. Table 1 presents the statistics comparing the performance of the baseline queries against the performance of the other strategies.

From table 1 we observe that the measures that have been extended with semantic similarity data appear to provide a more realistic account of the advantage of the various techniques over the baseline. The “soft” extended measures give more credit to all techniques, but relatively more to the baseline, so that the relative improvement appears smaller. This is indicated by the fact that the observed improvement of 160% in *PrecisionS@10* is more believable than one of 3142%. The same observation holds for an improvement in *F-scoreS@10* of 762% versus 6170%.

### 5 Conclusions

This paper addresses the problem of automatically evaluating topical retrieval systems using topical ontologies and semantic similarity data. After reviewing a definition of semantic similarity for topical ontologies and providing experimental evidence supporting

its effectiveness, we have proposed an evaluation framework that includes classical and adapted performance metrics derived from semantic similarity data.

Metrics that rely on semantic similarity data have also been used in the evaluation of semi-supervised topical search systems [17]. However, the use of semantic similarity data does not need to be limited to the evaluation of topical retrieval system. In [19] semantic data is used to evaluate mechanisms for integrating and combining text and link analysis to derive measures of relevance that are in good agreement with semantic similarity. Phenomena such as the emergence of semantic network topologies have also been studied in the light of the proposed semantic similarity measure. For instance, it has been used to evaluate adaptive peer based distributed search systems. In this evaluation framework, queries and peers are associated with topics from the ODP ontology. This allows to monitor the quality of a peer’s neighbors over time by looking at whether a peer chooses “semantically” appropriate neighbors to route its queries [1]. Semantic similarity data was also used for grounding the evaluation of similarity measures for social bookmarking and tagging systems [28, 21]. In the future, we expect to adapt the proposed framework to evaluate other information retrieval applications, such as classification and clustering algorithms.
